RESEARCH MEMORANDUM

COMPARATIVE DISPERSION DATA FROM GROUND-LAUNCHED

2.25-INCH ROCKETS EQUIPPED WITH

CRUCIFORM AND MONOPLANE FINS

By Paul E. Purser

SUMMARY

About 150 rounds of 2.25-inch subcaliber aircraft rockets, equipped with standard cruciform fins and with twisted monoplane fins, were ground-launched at the Langley Pilotless Aircraft Research Station at Wallops Island, Va. These tests provided dispersion data for use in evaluating the effectiveness of twisted monoplane fins for rocket stabilization.

The data indicated no significant difference in dispersion for rockets equipped with cruciform fins, with monoplane fins having 4° of twist at the fin tip, and with monoplane fins having 8° of twist.

The monoplane-fin rockets showed a small increase in range to impact over the cruciform-fin rockets. Mean deflections in crosswind firings were slightly smaller for the monoplane-fin rockets than for the cruciform-fin rockets but the differences may not be statistically significant in view of the relatively small number of rounds fired.

INTRODUCTION

An analysis and a brief flight investigation by the National Advisory Committee for Aeronautics has shown that bodies may be stabilized in flight by the use of twisted monoplane fins rather than the usual cruciform or triform fin arrangements. These studies, reported in references 1 and 2, did not provide any quantitative data on such items as the effect of fixing the monoplane fins to the body and thus including the body inertia in the rolling system, the dispersion of monoplane fin bodies such as rockets or bombs, the actual static and dynamic stability of such bodies, or the problems involved in launching or releasing monoplane-fin bodies from aircraft. The present tests were undertaken to provide data

on the effects of fixing the monoplane fins to the body and on the dispersion of monoplane-fin rockets. The tests consisted of measurements of the dispersion of ground-launched 2.25-inch subcaliber aircraft rockets equipped with cruciform fins and with twisted monoplane fins. The dispersion data obtained in these tests are presented and discussed herein.

SYMBOLS

ω_θ^2	pitch-frequency parameter, $\left(\frac{\omega_y}{p}\right)^2$
ω_ψ^2	yaw-frequency parameter, $\left(\frac{\omega_z}{p}\right)^2$
p	rate of roll, rps
ω_y	pitch frequency, $\frac{1}{2\pi} \sqrt{\frac{-C_{m\alpha} 57.3 q S d}{I_y}}$, cps
ω_z	yaw frequency, $\frac{1}{2\pi} \sqrt{\frac{C_{n\beta} 57.3 q S d}{I_z}}$, cps
$C_{m\alpha}$	variation of pitching-moment coefficient with angle of attack per deg
$C_{n\beta}$	variation of yawing-moment coefficient with angle of sideslip per deg
I_y	moment of inertia in pitch, 0.195 slug-ft ²
I_z	moment of inertia in yaw, 0.195 slug-ft ²
I_x	moment of inertia in roll, 0.0036 slug-ft ²
d	maximum body diameter, ft
S	maximum body cross-sectional area, sq ft
q	dynamic pressure, lb/sq ft

CONFIDENTIAL

ROCKETS, TESTS, AND EQUIPMENT

Rockets

The rockets used were standard 2.25-inch subcaliber aircraft rockets, designated 2.25TA001 or 2.25TA002 in reference 3. Approximately 50 rounds were fired with standard cruciform fins of the type shown in figure 1(a). Approximately 100 rounds were fired with twisted monoplane fins, also shown in figure 1(a). Half of the monoplane-fin rounds had a fin twist of 4° at the tip and half had a twist of 8° at the tip. The direction of twist was such as to produce a clockwise roll as viewed from the rear. The fins were twisted in a simple jig that allowed the application of a pure torque at the tip. The fact that the fins were thin plates, however, resulted in a twist configuration, as shown in figure 1(b), that produced effectively leading-edge and trailing-edge flaps as well as a twisted center portion of the chord plane. Figure 1(b) illustrates the final twist mode and average values of twist angles measured on each fin panel of 14 of the monoplane-fin rockets.

Tests

As shown in table I, the test program was divided into 5 lots of 30 rounds each. Each lot was equally divided among standard cruciform-fin rockets, 4° monoplane-fin rockets, and 8° monoplane-fin rockets.

Lots 1 to 5 were intended to provide angular deflection measurements up to a slant range of about 1,000 feet for several values of crosswind velocity and for two launching elevation angles. The data obtained and presented were lateral and vertical deflection in mils and slant range in feet. A few rounds of lots 1 to 5 were tracked by CW Doppler velocimeter and NACA modified SCR 584 position radar sets. Records were not taken on the position radar for these rounds, the operator simply noted the general appearance of the flight path and the range at impact.

Launcher

The launcher used was a rail type as shown in figure 2. The launcher length measured from the center of the rear launching lug to the end of the rails was $48\frac{7}{8}$ inches.

Cameras

Deflection data.-- The deflection data were obtained with a 70-millimeter rapid-sequence Hulcher camera mounted in a protective

frame beneath the launcher rail. (See fig. 2.) The camera was operated at approximately 15 frames per second. The lens used was a 305-millimeter focal length K-24 aerial camera lens adapted to the 70-millimeter camera. The camera was aligned parallel to and directly below the center line of the rail launcher. The vertical separation of the center lines of the camera and of a rocket resting on the launcher rail was 0.95 foot. The camera field of view was approximately ± 114 mils in the vertical plane and ± 93 mils in the lateral plane.

Rolling-velocity data.- Some rolling-velocity data were obtained with a 16-millimeter Mitchell camera hand-tracked from a position directly behind the launcher. The camera was operated at approximately 125 frames per second. The rocket fins were painted bright yellow and color film was used to provide better definition of fin position in space.

Axis System

The lateral and vertical deflections are referenced to the line of sight which is an extension of the rocket center line when the rocket is on the launcher. The range used was the slant range to points along the rocket flight path except for some data which are presented as true horizontal range to impact.

DATA REDUCTION AND ACCURACY

Deflection Data

The angular deflection data for round 1 of lot 1 are plotted in figure 3, to illustrate the general quality and amount of data obtained from each round. The following paragraphs discuss the data reduction procedures used and the estimated accuracy of various portions of the data.

The lateral and vertical deflection data were obtained from the 70-millimeter film by use of a transparent overlay gridded in mil measure. The smallest division on the grid was 2 mils. Considerations of grid size and repeatability of aligning the overlay and the film indicate that the basic deflection measurements are probably accurate to ± 2 mils. No parallax corrections were required for lateral deflection, but, because the camera was located 0.95 foot below the line of sight, the vertical deflection data did require parallax corrections. The accuracy of the parallax corrections depends directly on the accuracy of the range data to be discussed later; however, by the time the rocket has reached burn-out a range error of 35 feet would produce a change of only about $1/4$ mil in the parallax correction.

~~CONFIDENTIAL~~

~~CONFIDENTIAL~~

Range Data

Slant range for the first 1,000 feet along the trajectory or until the rocket image on the film was too faint to identify or until the rocket was no longer in the camera field of view was evaluated by integrating velocity data obtained from a CW Doppler velocimeter for several rounds. Comparison of these data indicated that a common range-against-time curve could be used for all rounds with a slant range of 385 feet at burnout. The time of burnout could be established within one camera frame (or 1/15 second), thus, from near burnout to 1,000-foot range, the slant range is probably correct within ± 35 feet (determined from $\pm \frac{1}{2} \times \frac{1}{15} \times \text{maximum velocity}$). It was possible to determine the slant range between 10 and 100 feet at from 1 to 4 points for most of the rockets based on measurements of the span of the fin image on the camera film. This procedure is believed to have provided slant-range data accurate to ± 10 feet or less in the early part of the flight.

Roll Data

The rolling velocity data were obtained by differentiation of roll-position time histories obtained from frame-by-frame analysis of the 16-millimeter film taken at 125 frames per second. The film was projected on white paper and the roll position marked for each frame; the accuracy of the roll position determination varied from $\pm \frac{1}{6}$ revolution to $\pm \frac{1}{3}$ revolution depending on the clarity of the fin image on the film. The scatter of the data indicated that the rolling velocity could be determined to $\pm 1\frac{1}{2}$ revolutions per second when evaluated over intervals of 10 to 20 frames.

Crosswind Data

Wind velocity and direction measurements used in determining the crosswind velocity for each round were obtained from a recording Bendix-Friez Aerovane. The measuring instrument was located at an altitude of 27 feet about 50 feet from the launcher. No measurements were made of the variation of wind velocity and direction with altitude.

The data as presented are believed correct within the following limits:

Wind velocity, fps	± 1.5
Wind direction, deg	± 2

~~CONFIDENTIAL~~

~~CONFIDENTIAL~~

Overall Accuracy

Considering the various accuracy values noted in the preceding paragraphs and the shapes of the curves presented in figure 3, the short-range data presented are believed to be correct within the following limits:

Indicated slant range, ft	Slant range, ft	Accuracy of -	
		Lateral deflection, mils	Vertical deflection, mils
25	± 10	± 4	$+10, -25$
50	± 10	± 4	$+4, -6$
100	± 10	± 4	± 4
200	± 25	± 3	± 3
385 (burnout)	± 35	± 2	± 2
770 (twice range at burnout)	± 35	± 2	± 2
1,000	± 35	± 2	± 2

RESULTS AND DISCUSSION

Stability of Monoplane-Fin Rockets

Theory and background.- An analytical study of the possibility of using rolling to stabilize a body, such as a monoplane-fin rocket, that would normally be stable in either the pitch or yaw plane but unstable in the other plane appears in reference 1, an analysis of the effects of rolling on the longitudinal stability of aircraft. Reference 2 presents the results of a brief experimental verification of the effects of rolling in stabilizing bodies that would normally be stable in only one plane. The data of reference 2 were only qualitative in nature and thus did not provide information on the degree of stability actually achieved or on the possible difference in dispersion between cruciform-fin and monoplane-fin rockets. The analysis of reference 1 shows that if a body is stable in one plane and unstable in the other, stability may be achieved by forcing the body to roll at a rate (in revolutions per second) that is equal to or greater than the natural frequency (in cycles per second) in the stable plane. There are additional requirements that tend to limit the roll rate if the ratio of stability in the unstable plane to the stability in the stable plane is large. The study of reference 2, however,

~~CONFIDENTIAL~~

~~CONFIDENTIAL~~

indicated that configurations similar to those used in reference 2 and in the present tests could be modified over rather wide ranges without exceeding the stability limits.

Data for present tests.- Some stability data for the rockets used in the present tests are presented in figures 4 and 5. The roll and pitch frequencies of the 4^0 monoplane-fin rockets are presented in figure 4 along with velocity and time data for the early stages of the flight. The velocity time history was calculated from known mass and thrust characteristics of the rocket and was checked by measurements of time and distance made with a 35-millimeter Fastax camera during the first 8 feet of travel for a few rounds and by Doppler radar measurements of maximum velocity. The rockets had a velocity of about 120 fps on leaving the launcher and reached a maximum velocity of 1,170 fps at 0.65 second after firing. The pitch frequency was calculated from estimates of the stability and checked against the value of oscillation distance of 126 feet given in reference 3. The yaw period (imaginary) was calculated from the body-alone portion of the stability estimates. The roll frequency, as previously noted, was obtained from the film records. The steady-state values of the measured roll frequency are considerably higher than values calculated from strip theory for rigid fins. The difference is believed attributable to aeroelastic effects on the thin metal fins of the rocket. The plots of figure 4 show that the roll frequency exceeded the pitch frequency (which is the requirement for stability) very early in the flight, the cross-over point was at about 0.17 second which corresponds to velocity of about 325 feet per second and a range of about 30 feet. Figure 5 is a stability chart as presented in reference 1 and has superimposed on it a time-trace of the stability characteristics of the 4^0 monoplane-fin rocket. Figure 5 shows that the monoplane-fin rockets are well within the stable region after less than 0.2 second of flight.

Presentation of Results

Angular-deflection data and wind data for all lots are presented in figures 6 to 20. Table I, which presents the test program, may be used as an index to those figures. The data on lateral dispersion and cross-wind effects on lateral deflection are summarized in figures 21 and 22 and in table II. Data on the dispersion at impact are summarized in table III.

General Characteristics of Rocket Flight Paths

Although the primary purpose of this paper is the presentation of comparative dispersion data for cruciform-fin and monoplane-fin rockets, a review of the general characteristics of the flight paths of ground-launched rockets may be worthwhile to many readers. Such a review may

~~CONFIDENTIAL~~

be based to a large degree on the data of figure 3. In considering these data one must remember that the deflections presented are angular values and that the actual distance between the flight path and line of sight is the product of range and angular deflection. Consider first the lateral deflection at a 12-foot range - this value of 4 mils corresponds to a distance of 0.048 foot or about 1/2 inch, this deflection is probably a result of thrust malalignment although irregularities in the launcher rails may be a contributing factor. Later in the flight, at 70-foot range, the 20-mil deflection corresponds to a distance of 1.4 feet and probably results from a combination of crosswind effects and fin malalignment. During burning, a stable rocket tends to weathercock into the wind and the thrust then drives the rocket up wind. The angle through which the rocket tends to turn in a given crosswind may be increased or decreased by fin malalignment but the rate of turning decreases as the rocket forward velocity increases so the crosswind effect tends to diminish as the rocket continues to accelerate. After burnout the rocket would tend to drift down wind, fin malalignment, depending on its direction, might increase or decrease this drift. The oscillation that occurs near burnout is probably due primarily to a sudden change in the direction of the crosswind effect but may also be due, to some extent, to momentary thrust malalignment resulting from nozzle separation at low pressure during burnout or from propellant slivers being caught in the nozzle during the burning-out process.

Considering the vertical deflection, any crosswind would have effects similar to those noted for the lateral deflection. For this particular round, however, the actual wind direction and the low launching angle combined to result in only a small vertical crosswind component and the major effects on the vertical deflection are the gravity effects noted in figure 3. As the rocket leaves the launcher, the forward support becomes free before the rear support; thus gravity forces acting at the rocket center of gravity induce a nose-down pitch and pitching rate; the thrust then drives the rocket down and the resulting deflection is called gravity tip-off. For stable rockets the gravity tip-off effect decreases as the rocket accelerates since the increased aerodynamic forces tend to reduce both the pitch angle and pitching rate. The burnout oscillation in the vertical plane is similar to that noted previously in the lateral plane. After burnout, the rocket continues under the influence of gravity, thus undergoing an increasing downward vertical deflection known as gravity drop. The apparent gravity tip-off and gravity drop may both be either increased or decreased by fin or thrust malalignment. The effects of fin and thrust malalignment may be decreased by imparting spin to the rocket provided the spin rate is sufficiently higher than the pitch and yaw natural frequencies to avoid resonance and instability.

~~CONFIDENTIAL~~

The following table summarizes the major items affecting rocket deflection and dispersion, and it indicates possible means of reducing the effects of these items:

Item	Means of reducing effects
Thrust malalignment and launcher irregularities	Increase static stability or increase velocity at launch by increasing length of ground launchers. For high-speed air-launching, zero-length launchers may reduce disturbances.
Crosswind effects	Increase velocity at launch, reduce static stability to near neutral.
Fin malalignment	Increase stability, impart spin at rate higher than natural pitch and yaw frequencies.
Gravity tip-off	Increase velocity at launch, release front and rear of rocket from launcher simultaneously.
Gravity drop	Increase velocity of rocket during complete flight.

Deflection and Dispersion Data

In general the deflection and dispersion data presented in figures 6 to 20 show the various effects noted in the preceding discussion of figure 3. There appear to be no major differences in the deflection data for the three rocket configurations used.

Figures 21 and 22 present statistical summaries of the lateral deflection data as plots of mean lateral deflection in mils against mean crosswind in feet per second for each lot at burnout range and at twice burnout range. Also shown is the lateral dispersion expressed as the standard deviation of the deflection from its mean value for each lot. The procedures used in determining the mean and standard deviation are given in the appendix. The slopes at 2 mils/fps faired through the data represent an average value for the effect of crosswind on the deflection of ground-launched rockets according to some British sources. The data in figures 21 and 22 appear to fit this average value of crosswind effect fairly well. The data appear to show slightly smaller crosswind effects for the monoplane-fin rounds than for the cruciform-fin rounds. Although

statistical reliability checks listed in the appendix indicate the data to be relatively reliable, the small number of samples in each lot probably does not justify any conclusion other than that the crosswind effects are approximately equal for the three rocket configurations.

The deflection and dispersion values shown in figures 21 and 22 are summarized in table II. The root-mean-square values of standard deviation shown in table II indicate no significant difference among the three types of rocket whether or not one includes the values for lot 4 which the statistical checks in the appendix indicated to be the least reliable lot. Ignoring lot 4 gives mil dispersion values of 25.7 and 27.75 for the cruciform-fin rockets - these values are slightly larger than the value of 23 listed in reference 3. The present tests, however, used a 4-foot launcher rather than the 7-foot launcher listed in reference 3 and would be expected to show slightly higher dispersion values.

Impact-Range Dispersion

As noted in the section entitled "Tests" a few rounds were tracked with the NACA modified SCR 584 radar and although no records were taken the operator's notes provide some data on range to impact. The impact-range data are summarized in table III. These data, although few in number, show slightly greater mean range for the monoplane-fin rockets than for the cruciform-fin ones. The range dispersions for the cruciform-fin and 4° monoplane-fin round are about equal. The greater dispersion shown for the 8° monoplane rounds may or may not be significant in view of the small sample size considered (4 rounds).

CONCLUDING REMARK

The data from the present tests indicate that fixing the monoplane fins to the body had no drastic effects on stability and that there were no significant differences in the dispersion and crosswind effects of cruciform-fin and monoplane-fin rockets.

APPENDIX

STATISTICAL PROCEDURES

The mean values of deflection, crosswind velocity, and range and the dispersion or standard deviations of these values were calculated by the following procedures:

Mean values were determined by

$$\bar{x} = \frac{\sum (x)}{n}$$

where x is individual values of deflection, crosswind velocity, and range; n is number of samples; and \bar{x} is mean value

$$d = \frac{\sum |x - \bar{x}|}{n}$$

where d is mean deviation or average scatter of values about mean

$$s.d. = \sqrt{\frac{\sum (x - \bar{x})^2}{n - 1}}$$

where $s.d.$ is standard deviation of values about mean and is the usual statistical measure of dispersion. The value $(n - 1)$ rather than n was used because of the relatively small sample size in each lot.

Checks on Statistical Reliability

Various checks were made on the statistical reliability of the data.

The first test was a comparison of the ratio $\frac{d}{s.d.}$ for each lot with the standard value of $\frac{d}{s.d.} = 0.798$ for "normal" or "Gaussian" distribution. Values of $\frac{d}{s.d.}$ for the lateral dispersion of the various lots of rockets ranged from 0.608 to 0.884. (See table II.) This range of values for $\frac{d}{s.d.}$ indicates fairly normal distribution.

The reliability of the samples was also checked by performing the following steps (based on refs. 4 and 5) on the data:

(1) From the range between extreme values in each sample w find the mean range \bar{w} and the standard deviation σ_w of the ranges using $n - 1$ instead of n for small samples.

(2) Calculate the following:

$$\alpha = \frac{\pi}{\sigma_w \sqrt{3}}$$

$$u = \frac{\pi \bar{w} - 2\gamma \sigma_w \sqrt{3}}{2\pi}$$

where $\pi = 3.14$ and $\gamma = 0.57722$

(3) Find R for each w , where $R = \alpha(w - 2u)$

(4) The range for each R which falls outside the limits $-1.75 \leq R \leq 5.35$ is then from a poor sample (for a 95 percent confidence level.) Shown in table IV are values of R obtained by performing this test on the samples.

In general the test indicated the data to be fairly reliable. Lot 4 for the cruciform fins, lot 2 for the 4° monoplane fins, and lot 4 for the 8° monoplane fins appeared to be possibly somewhat less reliable than the other lots.

TABLE II.- SUMMARY OF 2.25-INCH ROCKET LATERAL DISPERSION DATA

Fins	Lot	Mean crosswind velocity, fps	At burnout range (385 ft)			At twice burnout range (770 ft)			Remarks
			Mean deflection, mils	Standard deviation, mils	$\frac{\text{Mean deviation}}{\text{Standard deviation}}$ (a)	Mean deflection, mils	Standard deviation, mils	$\frac{\text{Mean deviation}}{\text{Standard deviation}}$ (a)	
Cruciform	1	17.41	28.67	15.77	0.845	37.20	23.41	0.813	Root-mean-square standard deviation of all lots = 31.63 at burnout, = 42.40 at twice burnout range. Ignoring lot 4, values are 25.70 and 27.75
	2	25.36	64.30	22.12	.798	67.57	20.81	.806	
	3	11.96	43.00	26.73	.798	42.00	22.53	.843	
	4	-14.62	-26.50	48.56	.676	-19.00	76.86	.859	
	5	2.17	1.90	34.50	.884	-3.62	39.9	.793	
4° Monoplane	1	22.10	13.83	21.11	.608	30.50	15.11	.711	Root-mean-square standard deviation of all lots = 29.10 at burnout, = 30.08 at twice burnout range. Ignoring lot 2, values are 25.05 and 26.20
	2	27.82	41.10	41.53	.867	26.25	39.51	.702	
	3	11.46	31.43	22.55	.758	35.67	25.57	.787	
	4	-11.74	-17.20	25.01	.633	(b)	(b)	(b)	
	5	2.22	13.67	30.50	.823	13.80	34.3	.858	
8° Monoplane	1	15.70	-2.07	29.13	.768	4.30	31.96	.667	Root-mean-square standard deviation of all lots = 43.69 at burnout, = 39.41 at twice burnout range. Ignoring lot 4, values are 27.21 and 23.91
	2	27.24	61.94	29.50	.732	57.43	15.22	.748	
	3	(b)	(b)	(b)	(b)	(b)	(b)	(b)	
	4	-13.88	-31.12	73.58	.846	-26.17	67.06	.781	
	5	2.64	-15.43	22.40	.800	-19.17	21.50	.783	

^aRatio of 0.798 indicates data have "normal" or "Gaussian" distribution.

^bInsufficient data to justify statistical analysis.

TABLE III.- 2.25-INCH ROCKET IMPACT DISPERSION DATA

Fins	Lot	Round	Range at impact, yd (a)	Mean range at impact, yd	Standard deviation of range at impact, yd	$\frac{\text{Mean deviation}}{\text{Standard deviation}}$

	5	6	5,530			
	5	15	5,350			

^aData from radar operator's notes.

TABLE IV.- STATISTICAL CHECK OF DATA

Fins	Lot	R (a)	
		At burnout range	At twice burnout range
Cruciform	1	-1.46	-0.19
	2	.72	-.13
	3	1.07	-.19
	4	3.22	3.20
	5	2.38	3.08
4° Monoplane	1	.38	-1.24
	2	4.36	3.04
	3	.51	1.39
	4	-.08	-----
	5	.60	1.54
8° Monoplane	1	.94	2.07
	2	2.68	-.73
	3	-----	-----
	4	2.28	3.22
	5	-1.34	.06

^aValue of R should be between -1.75 and 5.35 for 95% confidence level (see appendix).
